Abstract. Secondary Organic Aerosol (SOA) affects atmospheric composition, air quality and radiative transfer, however major difficulties are encountered in the development of reliable models for SOA formation. Constraints on processes involved in SOA formation can be obtained by interpreting the speciation and evolution of organics in the gaseous and condensed phase simultaneously. In this study we investigate SOA formation from dark α-pinene ozonolysis with particular emphasis upon the mass distribution of gaseous and particulate organic species. A detailed model for SOA formation is compared with the results from experiments performed in the European PHOtoREactor (EUPHORE) simulation chamber, including on-line gas-phase composition obtained from Chemical-Ionization-Reaction Time-Of-Flight Mass-Spectrometry measurements, and off-line analysis of SOA samples performed by Ion Trap Mass Spectrometry and Liquid Chromatography. The temporal profile of SOA mass concentration is relatively well reproduced by the model. Sensitivity analysis highlights the importance of the choice of vapour pressure estimation method, and the potential influence of condensed phase chemistry. Comparisons of the simulated gaseous- and condensed-phase mass distributions with those observed show a generally good agreement. The simulated speciation has been used to (i) propose a chemical structure for the principal gaseous semi-volatile organic compounds and condensed monomer organic species, (ii) provide evidence for the occurrence of recently suggested radical isomerisation channels not included in the basic model, and (iii) explore the possible contribution of a range of accretion reactions occurring in the condensed phase. We find that oligomer formation through esterification reactions gives the best agreement between the observed and simulated mass spectra.

1 Introduction

Secondary Organic Aerosol (SOA) has received significant interest because of its potential impact on climate, air quality and human health (e.g. Kanakidou et al., 2005). Quantification of the impacts of SOA requires simulating SOA production and chemical speciation, and thus implementing processes leading to SOA formation in 3-D chemical transport models (e.g. Fuzzi et al., 2006). SOA is formed by nucleation and/or condensation onto pre-existing particles of low volatility degradation products produced during the oxidation of Volatile Organic Compounds (VOC) (e.g. Kanakidou et al., 2005; Seinfeld and Pankow, 2003; Kroll and Seinfeld, 2008; Hallquist et al., 2009). However, the sheer number of individual compounds involved in gas-phase oxidation leads to major difficulties in representing SOA formation on a theoretical basis (e.g. Goldstein and Galbally, 2007). SOA formation is commonly empirically parameterized on the basis of mass yields observed in smog chamber experiments (e.g. Odum et al., 1996). Comparisons of simulated SOA mass with in situ observations highlight a systematic underestimation of SOA production, increasing broadly with air mass ageing (e.g. Volkamer et al., 2006). The current
parameterizations used in 3-D models require improvements to represent (i) SOA formation under a wide range of atmospheric chemical and physical conditions and (ii) SOA chemical speciation and its evolution during air mass ageing.

Simulation of SOA formation and composition requires theoretical models that describe in detail (i) the formation of Semi-Volatile Organic Compounds (SVOC) from gaseous oxidation (initiated by reactions with OH, O3, NO3 or photolysis) of the VOC precursors, (ii) the partitioning of each individual SVOC between the gaseous and the condensed phases, and (iii) the potential reactivity of the condensed SVOC within the particulate phase. While such detailed mechanisms may be too large in size to be implemented in 3-D chemical transport models, their evaluation against laboratory chamber experiments is essential to evaluate and improve our understanding of processes involved in SOA formation.

A number of studies have reported comparisons between chamber experiments and detailed models for SOA production from a range of biogenic and aromatic organic compounds which are known to be major SOA precursors (e.g. Jenkin, 2004; Stroud et al., 2004; Johnson et al., 2004, 2005; Capouet et al., 2008; Xia et al., 2008). Results from these studies have shown that model predictions can differ significantly from observations (Jenkin, 2004; Stroud et al., 2004; Johnson et al., 2004, 2005; Xia et al., 2008). For example Jenkin (2004) had to apply a scaling factor of two orders of magnitude to all rate constants for gas/particle partitioning in a model to simulate the final SOA mass observed during an α-pinene chamber oxidation experiment. Model performances have also been found to vary with the experimental conditions (i.e. temperature, relative humidity, NOx levels, initial concentration of precursors) (Stroud et al., 2004; Johnson et al., 2004, 2005; Xia et al., 2008). For example, Xia et al. (2008) have shown that their model simulations of 22 α-pinene oxidation experiments reproduced the observed SOA mass to within a factor varying from $1.87 \times 10^{-4}$ to 1.57, depending upon experimental conditions. Finally, these studies have shown that results can significantly differ from one detailed SOA model to another. For the example of SOA formation from α-pinene oxidation, some models have difficulties in reproducing observed SOA mass to within an order of magnitude (Jenkin, 2004; Xia et al., 2008), whereas Capouet et al. (2008) have shown that their model simulated the SOA mass observed during 28 α-pinene photooxidation experiments performed under a wide range of photochemical conditions in most cases to within a factor of 2. Many of these problems with simulated SOA mass are a consequence of uncertainties in our understanding of the detailed processes involved in SOA formation.

At present, three major difficulties are encountered in the development of reliable models for SOA formation:

1. the gaseous chemical pathways leading to the formation of SVOC are far from fully identified. Gaseous oxidation produces a multitude of individual SVOC, possibly formed after several oxidation steps of the precursor (e.g. Aumont et al., 2005). The majority of SVOC remain uncharacterised in the gaseous as well as in the condensed phases (e.g. Hallquist et al., 2009). Furthermore, large uncertainties still exist over the degradation mechanisms of multi-functionalised organics (e.g. Kroll and Seinfeld, 2008). Therefore assumptions and simplifications are implemented in the chemical schemes which represent the formation of gaseous SVOC.

2. the reactivity of SVOC in the condensed phase is poorly understood. High molecular weight organics have been detected in the condensed phase (e.g. Jang et al., 2002; Gao et al., 2004; Kalberer et al., 2004; Tolocka et al., 2004; Hamilton et al., 2006). This evidence strongly suggests the presence of accretion reactions occurring in the condensed phase, such as peroxyhemiacetal formation, hemiacetal formation, aldol condensation or esterification, and/or in the gaseous phase, such as peroxy radical self reactions or Stabilized Criegee Intermediate (SCI) reactions with other oxygenates (e.g. Kroll and Seinfeld, 2008). Such reactions could enhance the uptake of organic material to the condensed phase and its subsequent retention (e.g. Jang et al., 2002; Czoschke et al., 2003; Jenkin, 2004; Johnson et al., 2004, 2005). To date few such oligomer species have been characterised, and chemical schemes representing the reactivity of SVOC in the condensed phase are largely conceptual (e.g. Jenkin, 2004; Johnson et al., 2004, 2005; Capouet et al., 2008).

3. the thermodynamic properties controlling the gas/particle partitioning of each SVOC are uncertain. The gas/particle partitioning of SOVOC is expected to occur via an absorption process (e.g. Pankow, 1994a; Pankow, 1994b). The absorption of each SVOC is then controlled by its saturation vapour pressure. Considering the large number of SVOC contributing to SOA formation, estimation methods are required to calculate this property in detailed models. However, the uncertainty in vapour pressure estimates for SVOC can reach several orders of magnitudes (e.g. Asher et al., 2002; Asher and Pankow, 2006; Camredon and Aumont, 2006; Clegg et al., 2008; Barley and McFiggans, 2010). These large uncertainties are then directly propagated through the gas/particle partitioning reactions, and hence to the calculated SOA mass.

Constraints on processes involved in SOA formation can be obtained from comparisons of detailed model simulations with laboratory experiments that track the distribution and the evolution of SVOC in both the gaseous and condensed phases.

The aim of the present paper is to explore SOA formation from the dark ozonolysis of α-pinene, with particular emphasis upon the distribution of gaseous and particulate SVOC. The reaction of α-pinene with ozone is a major source of atmospheric SOA (e.g., Kanakidou et al., 2005) and hence has been the subject of numerous studies. α-pinene ozonolysis provides a good test case as a relatively complete identification of gaseous and particulate products exists. The methodology is based on a comparison of observations carried out in a large atmospheric simulation chamber against simulations performed with a detailed model of gaseous and condensed phase composition. The experimental work was performed in the EUropean PHotoREactor (EUPHORE) facility, with analytical instrumentation selected to ensure comprehensive detection of organic species distributed within the gaseous and condensed phases. Key techniques for providing the entire mass spectrum of species were Chemical-Ionization-Reaction Time-Of-Flight Mass-Spectrometry (CIR-TOF-MS) (e.g., Blake et al., 2004) for on-line analysis of a wide range of gaseous organics and Liquid Chromatography and ElectroSpray Ionisation ion trap Mass Spectrometry (ESI-MS and LC-MSⁿ) (e.g., Hamilton et al., 2008) for off-line analysis of SOA filter samples. The EUPHORE facility, instrumentation used and experimental conditions are described in Sect. 2. A detailed chamber specific box model incorporating the complete gas-phase α-pinene oxidation scheme, extracted from the Master Chemical Mechanism version 3.1 (MCMv3.1) (Jenkin et al. 1997, 2003; Saunders et al., 2003; Bloss et al., 2005a), was coupled to a gas/particle partitioning module for comparison with observations. The SOA formation model is presented in Sect. 3. The results of simulations of SOA mass from α-pinene dark ozonolysis are presented in Sect. 4. The simulated and observed gaseous and particulate distributions of organics are compared in Sect. 5.

2 Experimental setup

2.1 The EUPHORE facility

The experiments were conducted at the EUropean PHotoREactor (EUPHORE) facility in Valencia (Spain) as part of the UK NERC-funded TRAPOZ (Total RAdical Production and degradation Products from Alkene OZonolysis) project. The EUPHORE facility consists of two outdoor atmospheric simulation chambers located on the roof of the Centro de Estudios Ambientales del Mediterraneo (CEAM) building. Technical details concerning the simulation chambers are given in Becker et al. (1996). Briefly, each hemispheric photo-reactor is ~200 m³ in volume and is constructed from Fluorine-Ethene-Propene film (FEP). The reactors are surrounded by retractable steel covers allowing both dark and photolysis experiments to be carried out. Fans located inside the chambers ensure rapid homogenized mixing. Experiments are carried out at ambient temperature and close to the atmospheric pressure. Losses from sampling into the analytical instruments, and any leakage, are compensated for by periodical introductions of purified air into the chamber (both chambers are marginally over pressurised in order to prohibit ambient air ingress). The analytical instrumentation is located on a platform directly under each reactor.

2.2 Analytical instrumentation

The analytical instrumentation coupled to the EUPHORE chamber during the experiments are listed in Table 1. The
facility is equipped with a range of instruments measuring the environmental conditions inside the chamber (temperature, pressure, humidity and photolysis rates). Standard monitors were used to follow the temporal evolution of inorganic species ($O_3$, CO, NO$_x$). The OH and HO$_2$ radical levels were measured on-line using Laser Induced Fluorescence (LIF) (Bloss et al., 2004).

Measurements of the temporal evolution of the gas phase degradation products were made using traditional analytical techniques permanently available at EUPHORE, namely a formaldehyde monitor and various chromatographic instruments (Gas Chromatography-Mass Spectrometer – GC-MS – and a High Performance Liquid Chromatography – HPLC). Details concerning the permanent EUPHORE instrumentation are also given in Becker et al. (1999). The chamber instrumentation was supplemented by a Chemical-Ionization-Reaction Time-Of-Flight Mass-Spectrometer (CIR-TOF-MS) (Blake et al., 2004; Wyche et al., 2007, 2009), for the detection of a wide range of VOC at the ppb – sub-ppb (parts-per-billion by volume) level.

The temporal evolution of aerosol physical characteristics (size, number and volume distribution) was provided by Scanning Mobility Particle Sizer (SMPS), combining a Differential Mobility Analyser (DMA) and a Condensation Particle Counter (CPC). Aerosol samples were collected onto filters at the end of each experiment and the composition was analysed off-line. Filters were extracted into high purity water (Hamilton et al., 2008), and the mass distribution profile of the sample was obtained using direct infusion of the water soluble extract (via a syringe pump) into an ElectroSpray Ionisation source coupled to an ion trap Mass Spectrometer (ESI-MS). The chemical structures of SOA components were obtained using reverse phase Liquid Chromatography, to separate individual components, and fragmentation patterns obtained using collision induced dissociation in the ion trap MS (LC-MS$^n$) (Hamilton et al., 2006, 2008).

### 2.3 Experimental protocol

The experiments were performed at levels of reactants approaching (i.e. relevant to) atmospheric conditions (see Table 2). In order to exclude photochemical effects, the experiments were performed in the dark with the chamber housing closed ($j(NO_2)<2×10^{-5} s^{-1}$). The ozonolysis experiments were carried out under NO$_x$-free conditions ([NO] and [NO$_2$] below the monitor detection limit of 0.2 and 0.5 ppb respectively) and low relative humidity ([$H_2O$]=2×10$^{15}$ molec cm$^{-3}$). Two types of experiments were performed. A first experiment was carried out to observe SOA formation from a mixture composed of $\alpha$-pinene and ozone. A second type of experiment involved the observation of SOA formation from a mixture composed of $\alpha$-pinene, O$_3$ and an OH scavenger. In our experiment, CO was used as the OH scavenger. The amount of CO added inside the chamber was selected in order to ensure more than 95% of the $\alpha$-pinene chemical removal was due to O$_3$.

An aliquot of SF$_6$ was introduced to the chamber as an inert tracer to determine the dilution rate. For the experiment with an OH scavenger, the carbon monoxide (manufactured purity >99%, used as supplied) was injected directly. Ozone, produced from a silent discharge in pure oxygen (Linde, purity of 99.999%) with a typical production rate of 20 ppb min$^{-1}$, was supplied to the simulation chamber in a flow of purified air. Subsequently a known liquid volume of $\alpha$-pinene (manufactured purity >99%, used as supplied) was evaporated by heating through a purified air stream flowing into the chamber. The aerosol sample for ESI-MS and LC-MS$^n$ chemical analysis was collected on 47 mm quartz-fibre filters for a period of ~1 h at a flow rate of 74 L min$^{-1}$, commencing when the $\alpha$-pinene level had fallen to ~20% of its initial peak. Samples were immediately frozen and kept below −15°C until analysis.

### 3 SOA modelling

#### 3.1 Gaseous chemical scheme

The complete detailed gas-phase oxidation scheme for $\alpha$-pinene was extracted from the Master Chemical Mechanism version 3.1 (MCMv3.1), which is directly accessible from the website: http://mcm.leeds.ac.uk/MCM. The MCM is a
near explicit mechanism describing the complete degradation of 135 primary emitted VOC into CO$_2$ and H$_2$O. The subset of the MCMv3.1 describing $\alpha$-pinene oxidation contains $\sim$320 organic species evolving according to 920 reactions (prior to being coupled to a suitable set of inorganic reactions). In photochemical simulation chamber experiments, heterogeneous wall losses and conversion reactions need to be characterised and taken into account. However, under the conditions of the experiments studied (i.e. dark and NO$_x$-free) these wall processes are expected to be minimal. Only ozone wall losses on the EUPHORE chamber were implemented in the box model with a kinetic rate of $3 \times 10^{-6}$ s$^{-1}$ (Bloss et al., 2005b). The protocol applied to derive the $\alpha$-pinene oxidation scheme is presented in detail in Jenkin et al. (2000) and Saunders et al. (2003). During NO$_x$-free dark ozonolysis experiments, the oxidation of $\alpha$-pinene can be initiated by both O$_3$ and OH. The first oxidation stages of these degradation processes as represented in the MCMv3.1 (under NO$_x$-free conditions) are briefly described below.

The first stages of O$_3$-initiated $\alpha$-pinene oxidation are shown in Fig. 1. The initial step consists of the concerted addition of ozone to the C=O double bond of $\alpha$-pinene, leading to the formation of an energy-rich primary ozonide. This ozonide is expected to undergo rapid bond cleavage and isomerisation, giving two ring opened excited Criegee Intermediates (CI) with a carbonyl substituent (denoted CI$_{O31}$ and CI$_{O32}$ in Fig. 1). The CI$_{O31}$ and CI$_{O32}$ are assumed to decompose to yield OH and peroxy radicals PR$_{O31}$, PR$_{O32}$ or PR$_{O33}$. These peroxy radicals react with HO$_2$ and other RO$_2$ leading to the formation of stable species either directly (S$_{O31}$ to S$_{O38}$) or after further RO$_2$/RO conversions and intermolecular isomerisations. These chemical pathways lead to the formation of various secondary organics including the first generation oxidation products previously observed such as formaldehyde, acetone, pinalic-3-acid, pinic acid and 10-hydroxy-pinonic acid (S$_{O39}$ to S$_{O311}$ respectively). The CI$_{O32}$ may also be stabilized by collisions. The thermally stabilized Criegee (PR$_{O34}$) may undergo bimolecular reactions with H$_2$O, CO and/or other oxygenated organics (or NO in the ambient atmosphere) to produce pinonaldehyde (S$_{O314}$) and pinonic acid (S$_{O315}$). Despite considerable

![Fig. 1. First oxidation pathways in the O$_3$-initiated $\alpha$-pinene oxidation mechanism as represented in the MCMv3.1. The framed compounds are stable first generation species. The dots indicate chemical pathways not represented explicitly on the figure.](image-url)
study, large uncertainties still exist over the possible fates of the Criegee intermediates that lead to the formation of observed secondary products during the O$_3$-initiated $\alpha$-pinene oxidation (e.g. Johnson and Marston, 2008).

The initial oxidation pathways involved in the OH-initiated $\alpha$-pinene oxidation are shown in Fig. 2. The initial step proceeds through the addition of OH to the $>\text{C}=$C$<$ double bond of $\alpha$-pinene, forming a secondary or tertiary hydroxyl-substituted alkyl radical. These alkyl radicals react rapidly with O$_2$ to form the corresponding peroxy radicals (denoted PR$_{OH1}$ and PR$_{OH2}$ in Fig. 2). A fraction of the tertiary alkyl radical is also assumed to isomerise by ring opening prior to O$_2$ addition, giving the peroxy radical PR$_{OH3}$. These peroxy radicals recombine with HO$_2$ and other RO$_2$ to form stable species (SOH$_1$ to SOH$_6$) or their corresponding alkoxy radicals (AR$_{OH1}$, AR$_{OH2}$ and AR$_{OH3}$). The alkoxy radicals AR$_{OH1}$ and AR$_{OH2}$ are assumed to exclusively produce pinonaldehyde (product SOH$_7$) after C-C bond scission and H abstraction by O$_2$. The AR$_{OH3}$ radical is considered to decompose into acetone (SOH$_8$) and a peroxy radical PR$_{OH4}$ which then follow the usual RO$_2$ reactions to give the SOH$_9$ to SOH$_{11}$ stable species. Theoretical studies have demonstrated the existence of a number of alternative pathways in the OH-initiated $\alpha$-pinene oxidation involving intramolecular isomerisations (e.g. Peeters et al., 2001; Fantechi et al., 2002; Vereecken and Peeters, 2004; Vereecken et al., 2007). These processes were not considered in our model, and it is important to note that the existence of these chemical pathways could lead to a different distribution of organic species formed during the gaseous oxidation and have a substantial impact on SOA formation.

3.2 Gas/particle partitioning of organic compounds

The gas/particle partitioning of organic compounds was implemented as described in Camredon et al. (2007). The absorption of each SVOC produced during $\alpha$-pinene ozonolysis was represented assuming a thermodynamic equilibrium between the gas and particle phases, as described in Pankow (1994a, b). The thermodynamic equilibrium for each SVOC was calculated using Raoult’s law:

$$P_i = x_i P_{i \text{ vap}}^\text{vap},$$

where $P_i$ is the equilibrium partial pressure of a species $i$, $x_i$ its mole fraction in the condensed phase, $P_{i \text{ vap}}^\text{vap}$ its vapour pressure as a pure liquid at the temperature of interest.
and $\gamma_i$ its activity coefficient in the condensed phase. The gas/particle equilibria were applied to the full set of stable (i.e. non-radical) organic species formed during $\alpha$-pinene oxidation (around 180 species as described in the MCMv3.1). As aerosol particles are expected to be composed of organic molecules with a similar structure, we make the approximation that $\gamma_i$ may be set to unity (e.g. Seinfeld and Pankow, 2003). The liquid vapour pressure (probably subcooled) of the organic species was estimated using the Myrdal and Yalkowsky method (Myrdal and Yalkowsky, 1997) coupled with the Joback structure/property relationship for boiling point estimates (e.g. Reid et al., 1986), considering its reliability for SVOC generated during gas-phase oxidation (Camredon and Aumont, 2006); alternative choices are discussed in detail in Sect. 4. No chemical reactions were implemented in the condensed phase.

### 3.3 Box model

The gas-phase kinetic and the gas/particle partitioning modules were implemented in a zero-dimensional box model (Martin, 2009). The two modules were solved by operator splitting and treated as consecutive operators. The gas-phase kinetic module was integrated with the CVODE solver as downloaded from the SUNDIALS (SUite of Non-linear and DiFferential/ALgebraic equation Solvers) website (https://computation.llnl.gov/casc/sundials/main.html). The absorptive gas/particle partitioning module was solved using the iterative method described in Pankow (1994b). The partitioning processes between the gas and condensed phases were solved with an operator time step of 1 min, as an operator time step below 5 min was required to prevent the introduction of errors associated with operator splitting.

The box model was initialised with the environmental conditions and initial concentrations shown in Table 2 in order to simulate the experimental conditions. The simulation was initialised at a time point corresponding to the precursor injection for the $\alpha$-pinene+O$_3$ experiment and the ozone injection for the $\alpha$-pinene+O$_3$+CO experiment (shown at time zero in Fig. 3). The observed injection profiles were implemented as a constant flux that reproduced the observed $\alpha$-pinene (for the $\alpha$-pinene+O$_3$ experiment) or ozone (for the $\alpha$-pinene+O$_3$+CO experiment) concentrations (Table 2). The simulations were performed with environmental parameters (temperature, relative humidity and dilution rate) averaged over each experiment duration, these parameters varying minimally. The chamber mixture is diluted during the experiment because of the periodical introductions of purified air in the chamber to compensate for losses from analytical sampling and also through leakage. The dilution rate was determined by following SF$_6$ concentration during each experiment as measured by FT-IR (Fourier Transform InfraRed), and was well described by a single first order decay (Table 2). Aerosol formed during an experiment is affected by both dilution and by depositional losses onto the chamber surfaces.

Both processes were combined into a global first-order loss with no dependence on aerosol size. At the end of each experiment, the majority (>80%) of the precursor ($\alpha$-pinene) was consumed and the particle size distribution of the aerosol remained unchanged. We assume that at this point, dilution and wall loss of particles were the dominant processes affecting SOA evolution. The aerosol loss rate was calculated from the decay of the total particle volume concentration at this point, prior to starting SOA filter collection.

### 4 Temporal profile of SOA mass

The simulated temporal profile of SOA mass is compared with that observed in Fig. 3 for the $\alpha$-pinene+O$_3$ and $\alpha$-pinene+O$_3$+CO EUPHORE experiments. The observed SOA mass concentration was determined assuming an aerosol density of 1.2 g cm$^{-3}$, as measured previously for SOA from $\alpha$-pinene ozonolysis (e.g. Zelenyuk et al., 2008). The temporal evolution of the precursors ($\alpha$-pinene and O$_3$) is also shown. The simulated $\alpha$-pinene concentration differs by less than 10 ppb from the observations. The ozone decay is however underestimated, especially for the experiment performed without a scavenger, with a maximum difference

![Fig. 3. Temporal profile of SOA mass (red), $\alpha$-pinene (blue) and O$_3$ (green) during the $\alpha$-pinene+O$_3$ (a) and the $\alpha$-pinene+O$_3$+CO (b) EUPHORE experiments. Lines are the simulated results.](image-url)
in O\textsubscript{3} concentrations of 20 ppb. A rapid formation of SOA is observed as soon as the \(\alpha\)-pinene is oxidized. SOA mass maxima of 230 and 90 \(\mu g\) m\textsuperscript{-3} were observed for the \(\alpha\)-pinene+O\textsubscript{3} and \(\alpha\)-pinene+O\textsubscript{3}+CO experiments after approximately 60 and 90 min, respectively. The simulated temporal profile of SOA mass is relatively well captured by the model both in terms of the shape and the magnitude. The modelled formation of SOA starts as soon as the simulation begins to reach a maximum after \(\sim 60\) and \(\sim 80\) min for the \(\alpha\)-pinene+O\textsubscript{3} and the \(\alpha\)-pinene+O\textsubscript{3}+CO experiments, respectively, which is temporally similar to the observed maxima. The maximum SOA mass concentration is overestimated by the model by around 40 \(\mu g\) m\textsuperscript{-3} (17\%) and 55 \(\mu g\) m\textsuperscript{-3} (61\%) for the \(\alpha\)-pinene+O\textsubscript{3} and \(\alpha\)-pinene+O\textsubscript{3}+CO experiments respectively. For these two \(\alpha\)-pinene experiments, the model simulates the observed SOA mass within a factor of 2. While this represents a good model performance, it is important to note the significant uncertainties inherent in the comparison of the measured and modelled SOA mass curves shown in Fig. 3:

- Vapour pressure estimation method. The Myrdal and Yalkowsky method coupled to the Joback estimates has recently been shown to systematically underestimate vapour pressures compared with experimental data, for a range of atmospherically relevant SVOC (Barley and McFiggans, 2010). The implementation of an alternative method to estimate vapour pressures would lead to different, potentially significantly lower, modelled SOA mass. A sensitivity study investigating the impact of vapour pressure estimates is presented in Sect. 4.2.

- Micro-physical processes. No diffusion limitations or nucleation processes were implemented within the model. This therefore implicitly assumes that these processes are not rate-limiting. In addition, potential SVOC loss to particles deposited on the chamber walls is not considered (Hildebrant et al., 2009). However, the loss of SVOC to the walls of the EUPHORE chamber is expected to be small considering the low surface/volume ratio (\(\sim 0.75\) m\textsuperscript{-1}) involved and in comparison to (modelled) losses from the dilution processes.

- Errors and omissions in the gas-phase chemical scheme (MCM). The MCM is a near-explicit chemical mechanism, necessarily incorporating some systematic mechanistic simplifications (for example, lumping of the organic peroxy-radical self and cross-reactions). Large uncertainties also exist with regard to the degradation chemistry of bi- and multi-functional oxygenated products. The MCM is likely to omit several “novel” degradation pathways for \(\alpha\)-pinene. For example, theoretical calculations have shown that peroxy and alkoxy radicals formed during \(\alpha\)-pinene oxidation could evolve by isomerisation leading to the formation of low volatility species (e.g. Peeters et al., 2001; Fantechi et al., 2002; Vereecken and Peeters, 2004; Vereecken et al., 2007). These pathways are not currently implemented in the MCMv3.1, and will lead to increase gas-phase SVOC formation and hence the simulated SOA mass. Such SVOC would also be expected to contribute to the observed gas- and condensed-phase mass spectra, and are considered in the context of the observed mass spectra in Sect. 5.2. Similarly, further oxidation steps of other minor product channels (not incorporated into the MCM scheme) could influence the gaseous formation of SVOC (e.g. Camredon et al., 2007). The use of a fully explicit mechanism to describe \(\alpha\)-pinene oxidation would likely increase the formation of SVOC and therefore the simulated SOA mass.

- Condensed phase reactivity. The implementation of condensed phase reactions, or heterogeneous reactions between the aerosol and gaseous (S)VOC, would be expected to enhance the uptake of SVOC into the condensed phase and hence increase the simulated SOA mass. A sensitivity study to explore this possibility is described Sect. 4.1.

4.1 Condensed phase reactivity

No condensed phase reaction was considered in the model. If we assume that the products of any condensed phase reaction are less volatile than their precursor reactants, the aerosol mass simulated here can be seen as a lower limit (e.g. Kroll and Seinfeld, 2008), all other factors (including vapour pressure estimation method) not withstanding. In order to assess the influence of SVOC reactivity in the condensed phase on SOA mass, a sink of condensed SVOC was implemented in the model. Each condensed SVOC, \(\text{SVOC}_{\text{i}}^{(a)}\), was considered to follow a pseudo first order loss process with a kinetic constant \(k_{\text{react}}^{(a)}\), leading to the formation of a non-volatile organic species, \(\text{nvoc}\):

\[
\text{SVOC}_{\text{i}}^{(a)} \rightarrow \text{nvoc}. \quad (\text{R1})
\]

This non-volatile organic species, \(\text{nvoc}\), was considered to remain in the condensed phase and to be inert chemically, representing a permanent sink of SVOC to the condensed phase. This loss process of each condensed SVOC was implemented in the box model at the same time step as the gas/particle partitioning processes of each organic, i.e. with an operator time step of 1 min. Simulations were performed considering a chemical lifetime for condensed SVOC \(\tau_{\text{react}}^{(a)}=1/k_{\text{react}}^{(a)}\) of 60, 30 and 5 min. The temporal profiles of these simulated SOA masses are also shown in Fig. 5a and b. As expected, the addition of a sink of SVOC in the condensed phase enhances the uptake of organics to the aerosol within simulated SOA mass. The simulated SOA maximum is increased by 35 (13\%), 60 (22\%) and 130 \(\mu g\) m\textsuperscript{-3} (48\%) during the \(\alpha\)-pinene+O\textsubscript{3} experiment and by 40 (28\%), 60 (41\%)
and 95 µg m$^{-3}$ (66%) during the $\alpha$-pinene+O$_3$+CO experiment, in comparison with the SOA maximum simulated with no condensed phase reactivity, for $t_{\text{react}}=60, 30$ and 5 min respectively. Generally, assuming the condensed phase lifetime of SVOC is of the order of 5 min or longer, the implementation of condensed phase reactions in the model would increase the simulated SOA mass by less than a factor of 2.

4.2 Vapour pressure estimates

The results of this study may be compared with that of Jenkin (2004), in which the MCM was used to simulate SOA formation during $\alpha$-pinene chamber ozonolysis experiments, performed under environmental conditions similar to this work. In the earlier study, negligible SOA concentrations were simulated in comparison with experiment, unless the equilibrium constants for gas/particle partitioning were increased by two orders of magnitude. Our approach differs from that of Jenkin (2004) in the method adopted to estimate the vapour pressures of SVOC. Jenkin (2004) have estimated the vapour pressure using a modified form of the Mackay method (Mackay et al., 1982) coupled with the Stein and Brown structure/property relationship (Stein and Brown, 1994) for boiling point estimates.

Figure 4 shows comparisons between vapour pressures estimated at 298 K in this study (i.e. with the Myrdal and Yalkowsky method combined with the Joback method for boiling points estimates, vapour pressure estimates referenced hereafter as $P_{\text{vap,M&Y,J}}$) with those estimated by Jenkin (2004) (i.e. with the modified Mackay method combined with the Stein and Brown method for boiling points estimates, vapour pressure estimates referenced hereafter as $P_{\text{vap,M&Y,S&B}}$) for a range of secondary species formed during $\alpha$-pinene oxidation, together with two other combinations: vapour pressures estimated using the Myrdal and Yalkowsky method combined with the Stein and Brown method and using the modified Mackay coupled with the Joback method (vapour pressure estimates hereafter referenced as $P_{\text{vap,M&Y,S&B}}$ and $P_{\text{vap,M&Y,J}}$ respectively). For this specific set of compounds, the $P_{\text{vap,M&Y,J}}$ vary over a large range, between around $10^{-3}$ to $10^{-13}$ atm. The $P_{\text{vap,M&Y,J}}$, with divergence between $P_{\text{vap,M&Y,J}}$ and $P_{\text{vap,M&Y,S&B}}$ of between 3 and 5 orders of magnitude for the “top ten” species simulated to have a dominant contribution to SOA formed under the conditions of the $\alpha$-pinene+O$_3$ EUPHORE experiment (open circles in Fig. 4). The use of $P_{\text{vap,M&Y,S&B}}$ in the SOA model employed in this work leads to zero SOA formation for the $\alpha$-pinene+O$_3$ and $\alpha$-pinene+O$_3$+CO EUPHORE experiments, in agreement with the findings of Jenkin (2004). The use of $P_{\text{vap,M&Y,S&B}}$ in the model leads also to zero SOA formation. The use of $P_{\text{vap,M&Y,J}}$ leads to an SOA maximum of approximately a factor of two lower than that obtained with $P_{\text{vap,M&Y,J}}$.

Recently, Barley and McFiggans (2010) have shown that the Myrdal and Yalkowsky method coupled with the Joback method for estimating boiling points significantly underestimates vapour pressures for a range of atmospherically relevant SVOC, and suggest that the Nannoolal methods for vapour pressure (Nannoolal et al., 2008) and boiling point (Nannoolal et al., 2004) estimation would provide more reliable results for SOA calculations. The 298 K vapour pressures for the “top ten” species in $\alpha$-pinene oxidation estimated using the Nannoolal methods (referenced hereafter as $P_{\text{vap,N}}$) are shown in Fig. 4. For these species, the $P_{\text{vap,N}}$ are systematically higher than the $P_{\text{vap,M&Y,J}}$, with divergences varying between a factor of 10.9 and 94.4, highlighting that the choice of vapour pressure estimation method is a critical factor in simulating SOA formation. Simulations performed with an increase of all vapour pressures ($P_{\text{vap,M&Y,J}}$) by factors of 10 and 100 in the SOA model, encompassing the range of vapour pressure scale factors found between $P_{\text{vap,M&Y,J}}$ and $P_{\text{vap,N}}$, are shown in Fig. 5. An increase of all $P_{\text{vap,M&Y,J}}$ by factors of 10 and 100 leads to SOA maxima which are factors of 2 and 6 respectively lower than that obtained with $P_{\text{vap,M&Y,J}}$ for the $\alpha$-pinene+O$_3$ experiment. The influence of vapour pressure is higher for the $\alpha$-pinene+O$_3$+CO experiment, with SOA maxima which are factors of 8 and 30 respectively lower than that obtained with $P_{\text{vap,M&Y,J}}$. In this experiment, the formation of SOA comes from first generation oxidation products from $\alpha$-pinene ozonolysis, as OH radicals are scavenged by CO. Therefore the simulated SOA formation shows a large sensitivity to the vapour pressure...
SOA formation from α-pinene ozonolysis was studied with a particular focus on the distribution of gaseous and particulate organic compounds. The organic speciation is illustrated here with modelled versus measured comparisons performed for the α-pinene+O₃ EUPHORE experiment.

5.1 gaseous phase VOC and SVOC

5.1.1 The observed CIR-TOF-MS mass spectrum

The distribution of gaseous organics was monitored using CIR-TOF-MS. Details of the instrument are given in Blake et al. (2004) and Wyche et al. (2007), hence only salient points required to interpret the CIR-TOF-MS m/z spectra are presented here. During the current experiments, sample air from the EUPHORE chamber was delivered continuously to the CIR-TOF-MS through a heated 50 cm long Teflon sampling line. Once within the instrument, the analyte molecules underwent chemical ionization via reaction with the hydronium ion, H₃O⁺. Using this method the reagent reacts with the analyte, R, via direct proton transfer to form a positively charged ion RH⁺:

\[ \text{H}_3\text{O}^+ + \text{R} \rightarrow \text{RH}^+ + \text{H}_2\text{O} \]  

(R2)

The proton addition occurs predominantly at the site of highest electronic density on the analyte, i.e. in order: acid, ketone, aldehyde, alcohol and hydroperoxide functional groups, for moieties of relevance to tropospheric oxidation (Blake et al., 2009). Once formed the RH⁺ ion can undergo fragmentation to produce an ionised daughter fragment (F⁺) and a neutral molecule (N) (McLafferty and Turecek, 1993):

\[ \text{RH}^+ \rightarrow \text{F}^+ + \text{N} \]  

(R3)

For molecules containing acid, aldehyde and/or alcohol functionalities, the most common fragmentation mechanism following proton transfer ionisation is water elimination (Smith and Spanel, 2005), e.g. for an alcohol ROH:

\[ \text{(ROH)}\text{H}^+ \rightarrow \text{R}^+ + \text{H}_2\text{O} \]  

(R4)

Following ionisation, analyte ions are accelerated by an electric field into a time-of-flight mass spectrometer for analysis. The analyte R is then observed in its protonated form (m/z [M+1]+, where M is the molar mass of the analyte R) and frequently, in the case of oxygenated compounds, also at the m/z of its dehydrated form (m/z [(M+1)−18]+) and/or at the m/z of its fragment ions, the most common being the allyl ion (CH₂=CHCH₂⁺, m/z 41), the n-propyl ion (CH₃CH₂CH₂⁺, m/z 43) or the acetyl ion (CH₃CO⁺, m/z 43) (Wyche et al., 2005; Blake et al., 2006). The relative contribution of RH⁺ and the various fragments i, F⁺, to the total signal is species dependent. The extent of fragmentation tends to increase...
Table 3. Characterized CIR-TOF-MS signatures for species of interest for α-pinene oxidation. The m/z of fragments ions and their relative abundances to the total signal have been identified by CIR-TOF-MS calibration\(^{(1)}\) and from literature Hellen et al. (2008)\(^{(2)}\). RA indicates relative abundance.

with the length of the carbon chain. Characterized CIR-TOF-MS mass spectral signatures for a number of species of interest for α-pinene oxidation are listed in Table 3. The mass resolution \((m/Δm)\) of the CIR-TOF-MS during the current experiments was around 1500. The CIR-TOF-MS spectra presented here were normalized to \(10^6\) \(\text{H}_2\text{O}^+\) ion counts, background subtracted and averaged over 10 min (Blake et al., 2004).

5.1.2 The simulated gaseous mass spectrum

A direct comparison of the simulated gaseous concentrations with the CIR-TOF-MS mass spectrum is difficult owing to the presence of numerous fragment ion counts in the spectrum. A simplified representation of this fragmentation has been considered to create a "simulated gaseous mass spectrum". The simulated gaseous mass spectrum has been constructed as follows:

1. \(m/z\) peaks for each species R:
   ions considered were \(\text{RH}^+\) giving a \(m/z\) \([\text{M}+1]^+\) peak, and in some cases fragmented forms, such as \(\text{RH}^+ - \text{H}_2\text{O}\) giving a \(m/z\) \([\text{M}+1] - 18\) peak and/or other \(F^+_i\) fragments giving a peak at their corresponding \(m/z\) through the following assumptions. For compounds having a characterized CIR-TOF-MS signature the relative contribution of each \(m/z\) peak was used, as given in Table 3. For other compounds it has been assumed that (1) protonated species having a chain length shorter than or equal to 3 carbons do not fragment and (2) protonated species containing an acid, aldehyde or alcohol moiety (following the acid, ketone, aldehyde, alcohol, hydroperoxide priority order for the protonated site on a multifunctional species) dehydrate at a value of 40% (representative of the known fragmentation fractions; see Table 3).

2. Intensity of the \(m/z\) peaks for each species R:
   the intensity of each \(m/z\) peak was assumed to be proportional to the simulated gaseous concentration of the species R scaled by their relative contribution;

3. Total \(m/z\) intensity at a resolution of 1 Da:
   the total intensity of each integer \(m/z\) peak was calculated by summing the intensities of all the ions between \(m/z - 0.5\) and \(m/z + 0.5\).

It is important to note that for compounds which do not have characterised fragmentation patterns (i.e. the majority of secondary species), this approach neglects fragments other than dehydrated ions of the protonated analyte. Furthermore, this method considers that the simulated signal intensity is proportional to the concentration, independent of the species, whereas in practice each species has a different ionisation efficiency, and hence a different CIR-TOF-MS response. In addition, the fraction of the analyte that dehydrates is fixed at 40%, a value that in reality is likely to differ significantly between species (Smith and Spanel, 2005). A quantitative comparison between the simulated and CIR-TOF-MS signal intensity is therefore not possible, but a qualitative comparison with the observations may be made.

5.1.3 Comparison of the gaseous mass spectra

The simulated gaseous mass spectrum is compared with the observed CIR-TOF-MS mass spectrum in Fig. 6 for scans recorded and simulated after 60 min reaction time (i.e. at peak SOA loading, see Fig. 3). The CIR-TOF-MS mass spectrum is shown on the upper y-axis. Around 35 peaks showing
the temporal signal of secondary species (products) formed during the experiment were recorded in the mass spectra between m/z 0 and 300 Da. The simulated gaseous mass spectrum is plotted on the lower y-axis. A total of 37 peaks, of which 26 represent non fragmented ions (RH+), were simulated by the model in the mass range m/z 0–300 Da. The close correspondence between many of the observed and simulated peaks indicates that the mass distribution of the major products is reasonably well reproduced. In the higher mass range (m/z > 100 Da), most of the peaks recorded by the CIR-TOF-MS are also present in the simulated m/z spectra. Some simulated peaks are not detected by the CIR-TOF-MS (such as m/z 201, 189, 187, 175 or 159). In the lower mass range (m/z < 100 Da), most of the observed peaks are not present in the simulation. These signals (such as at m/z 43, 93, 95 or 99) are likely to be fragment ions that are not considered in our simple fragmentation approach.

Species have been assigned to the major peaks detected by the CIR-TOF-MS on the basis of characterized CIR-TOF-MS signatures (see Table 3) and previous identification of secondary products formed from α-pinene oxidation (e.g. Yu et al., 2008). The proposed structures for these major compounds are shown in Table 4. Their simulated temporal evolution is compared with the CIR-TOF-MS measurements in Fig. S1 of the Supplementary material: http://www.atmos-chem-phys.net/10/2893/2010/acp-10-2893-2010-supplement.pdf. The main peaks arise from formaldehyde (m/z 31), formic acid (m/z 47), acetone (m/z 59), acetic acid (m/z 61), α-pinene (m/z 137, 81) and pinonaldehyde (m/z 169, 151, 109, 107). The simulated peaks for many of these major observed m/z signals are consistent with the CIR-TOF-MS measurements (see Fig. 6a), and their simulated temporal evolutions are in good agreement with the CIR-TOF-MS observations (see Fig. S1: http://www.atmos-chem-phys.net/10/2893/2010/acp-10-2893-2010-supplement.pdf). The exceptions concern the m/z of acetic acid which has a high intensity in the CIR-TOF-MS signal but is simulated to be formed at very low concentration, and formic acid which is not produced in the simulation. Formic and acetic acids signals present within the measurements are most likely a result of off-gassing from the chamber walls, which is often observed with such experiments (e.g. Rickard et al., 2009); such reactions are not represented in our chamber mechanism. It should also be noted that other larger molecular weight species can produce fragment ions of m/z 61 using the proton transfer technique. The simulated contribution of the identified compounds to the total concentration of gaseous species at a given molar mass (±0.5 g mol⁻¹) is also given in Table 4. These assigned compounds are calculated to make a dominant contribution (>70%) to their mass channel, indicating that the assigned species are the main product found at these m/z. However other species detectable by CIR-TOF-MS could also potentially contribute to an observed m/z peak. For example, glycolaldehyde is simulated to contribute 27% of the total concentration at m/z 61 compared with 73% from acetic acid, and 2-hydroxopinan-3-one which is simulated to contribute 15% to the total concentration at m/z 169 compared with 85% from pinonaldehyde.

Apart from pinonaldehyde, the major peaks present in the CIR-TOF-MS spectrum correspond to volatile species. Gaseous SVOC, of low volatility and hence most important for SOA formation, are generally expected to have a higher molecular weight and therefore are to be found at higher m/z. Figure 6b focuses on the gaseous mass spectrum for m/z greater than the protonated α-pinene ion (RH+ at m/z 137). Structures for the gaseous SVOC detected by the CIR-TOF-MS have been suggested on the basis of the simulated speciation, and are shown in Table 4 together.

![Fig. 6. Gaseous m/z spectra of the α-pinene+O3 EUPHORE experiment:](http://www.atmos-chem-phys.net/10/2893/2010/acp-10-2893-2010-supplement.pdf)

</table>
with their simulated contribution to the total concentration of gaseous species having the same molar mass (within ±0.5 g mol⁻¹). Their simulated temporal evolution is compared with the CIR-TOF-MS measurements in Fig. S2 of the Supplementary material: http://www.atmos-chem-phys.net/10/2893/2010/aqp-10-2893-2010-supplement.pdf. The temporal profiles are comparable with the model predictions within the precision of the experimental data with the exception of m/z 147 (see Fig. S2: http://www.atmos-chem-phys.net/10/2893/2010/aqp-10-2893-2010-supplement.pdf), indicating that the principal species contributing to the observed peak of m/z 147 may not be represented in the model. The simulated concentration at m/z 147 is however very small and the observed signal could also be explained by the formation of species not included in the MCMv3.1 or by fragments of analytes formed during the CIR-TOF-MS analysis. Most of these species, such as pinonic acid (RH⁺ at m/z 185), 4-oxopinonaldehyde (RH⁺ at m/z 183), pinonaldehyde (RH⁺ at m/z 169) and norpinonaldehyde (RH⁺ at m/z 155) have been previously identified as secondary products formed during α-pinene oxidation (e.g. Christoffersen et al., 1998; Yu et al., 1998, 1999, 2008; Glasius et al., 2000; Koch et al., 2000; Larsen et al., 2001; Lee et al., 2006; Ma et al., 2008). At the same mass channel as pinonic acid (RH⁺ at m/z 185), an hydroxypinonaldehyde is simulated to have a large contribution to the m/z 153 peak (63% compared with 26% from pinonic acid). An isomer of this hydroxyl pinonaldehyde has previously been identified by Yu et al. (1998, 1999) during α-pinene ozonolysis. The mass channel m/z 153 is explained in the simulation by the dehydrated form of protonated species (having an RH⁺ m/z of 171), such as 2,3-pinnadiol or pinalic-3-acid. Yu et al. (2008) have assigned m/z 153 to the protonated form, RH⁺, of pinene oxide. Pinene oxide is a first oxidation product of α-pinene ozonolysis formed with a yield of 3% (Berndt et al., 2003). The formation of pinene oxide is not included in the MCMv3.1, but could in reality contribute to the observed m/z 153 peak. However, the contribution of pinene oxide to the m/z 153 peak is expected to be low due to its extensive fragmentation in the CIR-TOF-MS (see Table 3). The observed peaks at m/z 149 and m/z 165 are absent in the simulated spectrum. Neither of these peaks correspond to first generation products formed by the alternative OH-initiated oxidation pathways of α-pinene identified by Peeters et al. (2001), Fantietchi et al. (2002), Vereecken and Peeters (2004) or Vereecken et al. (2007). Yu et al. (2008) have assigned the peak at m/z 165 to be the dehydrated fragment ion of 4-oxopinonaldehyde. The simulated RH⁺ peak at m/z 159 is absent in the CIR-TOF-MS data but could correspond to a dehydrated fragment at m/z 141. The MCM names of the species contributing to the simulated m/z 159 are C811OH, C890OH and C717OH. A number of simulated SVOC species of interest (m/z 201, 189, 187, 175) have not been detected by the CIR-TOF-MS either as a protonated parent ion or as a dehydrated fragment ion. However, species having a similar molar mass were found in the condensed phase (see Sect. 5.2). These species were possibly not detected by CIR-TOF-MS because: (i) they contribute mainly to the composition of the condensed phase, with gaseous concentrations under the CIR-TOF-MS detection limit (simulated concentrations were between 10 and 50 ppt) or (ii) they have very low vapour pressures and hence could condense onto the walls of the CIR-TOF-MS inlet line, although it is also possible that the mechanism is incorrect and these species are not in fact formed in the α-pinene oxidation system.

5.2 Condensed phase organic speciation

5.2.1 The observed ESI-MS mass spectrum

The mass spectral distribution of condensed organics was measured by ESI-MS. A detailed description of the instrument is given by Hamilton et al. (2008). As for the CIR-TOF-MS only details required to interpret the ESI-MS m/z spectra are briefly presented. The aerosol filter sampled at the conclusion of the experiment was extracted by sonication using water as a solvent (e.g. Hamilton et al., 2008). The extracted solution was directly infused into the electrospray ionisation source using a syringe pump and analysed using an ion trap mass spectrometer to obtain a mass distribution. Electrospray ionisation is a soft ionisation method expected to result in minimal fragmentation. The mass spectrometer was used both in positive and negative ionization modes. In positive ionisation, ions are produced by protonation or cationisation with sodium ions (Na⁺). The sodium ion adducts of the analyte R, [R+Na]+ dominate, leading to [M+23]+ ions for most oxygenated compounds. The sodium (present in the glassware used in the analysis) can in the case of oxygenated functionalities improve detection and sensitivity (Hamilton et al., 2008). Negative ionisation mode leads to formation of deprotonated ions [M−H]⁻ and gives a response primarily for species bearing an acidic hydrogen. The analyte, R, is thus observed as the [R+Na]+ ion at m/z [M+23]⁺ in the positive mode and as the [R−H]⁻ ion at m/z [M−1]⁻ in the negative mode. The ESI-MS mass resolution was around 1 Da.

5.2.2 The simulated condensed phase mass spectrum

A “simulated condensed phase mass spectrum” has been produced from the modelled SOA composition in the same way as for the gaseous mass spectrum, for comparison with the observed ESI-MS mass spectrum:

1. m/z peak for each species R: ions considered for the positive mode were the [R+Na]+ adducts giving a m/z [M+23]+ peak for all species and for the negative mode the [R−H]⁻ ions giving a m/z [M−1]⁻ peak for species bearing an acid functionality (i.e. CO(OH) or CO(OOH));

2. Intensity of the m/z peaks for each species R: the intensity of each m/z peak was assumed to be
proportional to the simulated concentration of the condensed species R;

3. Total \( m/z \) intensity at a resolution of 1 Da:
   the total intensity of each \( m/z \) peak was calculated by summing the intensities of all of the ions between \( m/z-0.5 \) and \( m/z+0.5 \).

As for the simulated gaseous signal, this approach assumes that the simulated signal intensity is proportional to the concentration, independent of species identity, whereas in practice the ESI-MS response will be dependent on the species’ ionisation efficiency. While a quantitative comparison is not possible, a qualitative comparison between the simulated and ESI-MS measured mass distributions may be made.

5.2.3 Comparisons of the condensed mass spectra

The ESI-MS measured spectra are shown in Fig. 7 on the upper y-axis for both the positive and negative ionisation modes. In the positive ionisation mode, a region of monomer type compounds (with \([R+Na]^+\) adducts at \( m/z \) between approximately 160 and 280 Da) is apparent, and a smaller region of oligomers (with \([R+Na]^+\) adducts at \( m/z \) between approximately 330 and 430 Da) can be clearly identified. These two regions are also present in the measured negative ionisation mode spectrum. However the signal in the oligomeric region is rather noisy and most of the peaks are probably due to contamination and in-source creation of acidic dimer artefacts (Muller et al., 2009). These are not formed in positive ionisation. The oligomers observed in positive ionisation mode are not artefacts of the instrument (they can be separated using LC). This oligomeric region is likely the result of accretion reactions of two monomers either in the aerosol or the gas-phase. These oligomers are homo or heterodimers (referred to hereafter simply as “dimers”). The positive ESI-MS and CIR-TOF-MS mass distributions are compared in Fig. S3 of the Supplementary material: http://www.atmos-chem-phys.net/10/2893/2010/acp-10-2893-2010-supplement.pdf. Here again, a direct comparison of the CIR-TOF-MS and ESI-MS mass distributions is not straightforward owing to the presence of numerous fragment ions in the CIR-TOF-MS spectrum. Only a small \( m/z \) range of the ESI-MS and CIR-TOF-MS spectra show matching peaks, with species having a molar mass between around 140 and 190 g mol\(^{-1}\) (such as 146, 156, 168, 170, 172, 182 or 184 g mol\(^{-1}\)). Some or all the species contributing to these peaks may therefore be present in both the gaseous and condensed phase simultaneously. Other peaks in this mass range are present in the ESI-MS spectrum but not in the CIR-TOF-MS spectrum. It is possible that these peaks correspond to fragments of analytes formed during the ESI-MS analysis. Species having a mass higher than 184 g mol\(^{-1}\) are only present in the ESI-MS spectrum. As noted above, these species may not be detected by CIR-TOF-MS as they contribute mainly to the composition of the condensed phase, or alternatively may not be observed due to inlet line losses.

Fig. 7. Condensed phase mass spectra of the \(\alpha\)-pinene+O\(_3\) EU-PHORE experiment using the mass spectrometer in (a) positive ionisation mode and (b) negative ionisation mode. The ESI-MS mass spectrum of the filter taken after the experiment is represented in black on the positive y-axis. The simulated condensed mass spectrum at the end of the experiment is shown in red on the negative y-axis. Labels show the \( m/z \) value of the more intense peaks.

The simulated condensed phase mass spectra are compared with the ESI-MS measured spectra in Fig. 7 on the lower y-axis for both the positive and negative ionisation modes. The observed and simulated peaks in the monomer region are in reasonable agreement for both the positive and negative ionisation spectra. The good correspondence for the positive ionisation indicates that the mass distribution of the products is well simulated, while the agreement for negative mode gives confidence in the assignment of acidic functionality. Therefore, the formation of the majority of the observed condensed phase monomer species can be explained by gas/particle partitioning of the SVOC formed during gas-phase oxidation. All of the peaks present in the simulated mass spectra were observed by the ESI-MS. A few species detected by the ESI-MS in the monomer region (such as \([R+Na]^+\) adducts at \( m/z \) 225 or 241 and a small section between 240 and 280 Da) were not present in the simulation. Gaseous compounds with a similar molar mass were
not detected by the CIR-TOF-MS. The mass distribution in the dimer region is not simulated as no accretion reactions were implemented within the model (see Sect. 5.3).

Structures for the condensed monomer species have been assigned to the major peaks detected by the ESI-MS in the positive and negative ionisation modes on the basis of the simulated speciation. The proposed species with their simulated contribution to the total concentration of condensed species at the same molar mass (±0.5 g mol⁻¹) are shown in Table 5. Aerosol extracts were also separated using LC and subjected to Collision Induced Dissociation (CID) to obtain fragmentation patterns, which were used to predict chemical structures of the SOA components. Simulated SOA components that can be identified in the collected aerosol, based on fragmentation patterns, are given in Table 5. Organic acids such as pinonic acid ([R+Na]⁺ adduct at m/z 207 and [R−H]⁻ at m/z 183), pinic acid ([R+Na]⁺ adduct at m/z 209 and [R−H]⁻ at m/z 185) or 10-hydroxypinonic acid ([R+Na]⁺ adduct at m/z 223 and [R−H]⁻ at m/z 199) are simulated to be present in the condensed phase, in agreement with the LC-MS² analysis and previous studies on SOA formation from α-pinene oxidation (e.g. Christoffersen et al., 1998; Hoffmann et al., 1998; Yu et al., 1999; Jang and Kamens, 1999; Glasius et al., 2000; Koch et al., 2000; Iinuma et al., 2004; Jaou et al., 2005). The [R+Na]⁺ adduct of pinonic acid at m/z 207 has the highest observed peak intensity of the positive mode. However a hydroxypinonaldehyde is simulated to contribute 54% to the total concentration of the [R+Na]⁺ adduct at m/z 207 and pinionic acid 35%. An isomer of hydroxypinonaldehyde has previously been identified in the condensed phase by Yu et al. (1999). Norpinic acid was also detected here within the condensed phase by LC-MS⁰ and has also been observed in previous studies (e.g. Kavouras et al., 1998; Glasius et al., 2000; Iinuma et al., 2004). In this study the concentration of norpinic acid is simulated to be very low, in both the condensed and gaseous phases. The simulated [R+Na]⁺ adduct at m/z 195 in the positive mode (which would correspond to norpinic acid) is explained by a dihydroxyaldehyde species, and the corresponding simulated [R−H]⁻ peak intensity at m/z 171 in the negative mode is very low in comparison to that observed. The formation of norpinic acid from gaseous oxidation could be underestimated in the MCMv3.1. However, the large contribution of norpinic acid to SOA formation from α-pinene ozonolysis has been questioned by Claeys et al. (2009) who have estimated in the MCMv3.1. However, the large contribution of norpinic acid from gaseous oxidation could be underestimated by the CIR-TOF-MS. The mass distribution in the dimer region is not simulated as no accretion reactions were implemented within the model (see Sect. 5.3).

5.3 Condensed phase oligomers

5.3.1 Reactivity in the condensed phase

As noted, the high molecular weight species detected by ESI-MS are probably homo or heterodimeric species. Among the reactions suggested to explain the formation of high molecular weight compounds in SOA, these dimers could result from the reaction of a pair of condensed monomers (e.g. Kroll and Seinfeld, 2008; Hallquist et al., 2009). The simulated speciation of the condensed monomers was used to explore the possible mass distribution of condensed dimers which would form according to various possible accretion reactions for comparison with the observed ESI-MS signal. The accretion reactions investigated were peroxyhemiacetal formation (e.g. Tobias et al., 2000; Tobias and Ziemann, 2000), hemiacetal formation (e.g. Jang and Kamens, 2001; Jang et al., 2002; Garland et al., 2006; Surratt et al., 2006), aldol condensation (e.g. Noziere and Riemer, 2003; Esteve and Noziere, 2005; Garland et al., 2006; Surratt et al., 2006; Casale et al., 2007) and acid anhydride and ester formation.
Table 5. Proposed structures (based on the simulation) for the major monomer compounds detected by the ESI-MS in the positive and negative ionisation modes for the α-pinene+O₃ EUPHORE experiment together with their simulated contribution to the total concentration of condensed species having a same molar mass (within ±0.5 g mol⁻¹). aStructure confirmed using LC-MS. bIsomer of a structure confirmed using LC-MS (with two carbons on the acid side rather than the aldehyde side).

</table>

(e.g. Gao et al., 2004; Hamilton et al., 2006; Muller et al., 2008). These potential reactions are shown schematically in Fig. 8. Combination reactions occurring in the gaseous phase followed by gas-particle partitioning, such as peroxy radical self reactions (e.g. Ziemann, 2002) and stabilized Criegee reactions with other oxygenates (Sadezky et al., 2006; Heaton et al., 2007; Zahardis and Petrucci, 2007), could also represent a significant pathway for formation of the observed dimers (e.g. Muller et al., 2009) but are not considered here.
5.3.2 The simulated condensed phase mass spectrum for dimers

For a given accretion reaction involving a pair of condensed monomers bearing functionalities $i$ and $j$, each simulated monomer $A$ having a function $i$ was combined with each simulated monomer $B$ having a function $j$. The mass of the dimer species formed $AB$ (or $AB-\text{H}_2\text{O}$ if dehydration occurs) was $M=M_A+M_B$, where $M_A$ is the molar masses of the monomers $A$ (or potentially $M_A+M_B-18$ if dehydration occurs). For each investigated accretion reaction a “simulated condensed phase mass spectrum” of the species $AB$ was produced for comparison with the observed positive ionisation mode ESI-MS mass spectrum where:

1. $m/z$ peak for each dimer $R$:
   - ions considered were the $[R+\text{Na}]^+$ adducts giving a $m/z$ $[M+23]^+$ peak for each dimer;

2. Intensity of the $m/z$ peaks for each dimer $R$:
   - the intensity of each $m/z$ peak was proportional to $n_i A \times n_j B \times C_A \times C_B$, where $n_i A$ is the number of occurrences of functional group $i$ within monomer $A$, and $C_A$ the simulated concentration of the monomer $A$ in the condensed phase, by analogy with the production rate $dC_{AB}/dt$;

3. Total $m/z$ intensity at a resolution of 1 Da:
   - the total intensity of each integer $m/z$ peak was calculated by summing the intensities of all the peaks between $m/z-0.5$ and $m/z+0.5$.

Comparison of the simulated condensed phase spectrum for dimers with the observed ESI-MS spectrum is exploratory considering that this approach is necessarily directly linked to the simulated composition of SVOC monomers present in the condensed phase.

5.3.3 Comparisons of the condensed dimer mass spectra

The simulated condensed-phase dimer mass spectra for those accretion reactions considered are compared with the observed mass spectrum under positive ionisation mode in Fig. 9. Many of the observed features in the dimer region of the measured spectrum ($[R+\text{Na}]^+$ adducts at $m/z$ between 300 and 500) are consistent with all of the accretion reactions considered, however peroxyhemiacetal and hemiacetal formation reactions fail to represent dimers with the lowest masses ($[R+\text{Na}]^+$ adducts at $m/z<360$) and lead to dimers with higher masses than those observed ($[R+\text{Na}]^+$ adducts at $m/z>440$) (Fig. 9a and b). Hemiacetal formation has previously been found to be thermodynamically unfavourable (Barsanti et al., 2004). Accretion reactions involving dehydration, such as aldol condensation and esterification, result in a better agreement between the simulated and observed dimer mass spectra (Fig. 9c and d). Dehydration has already been observed to take place during dimer formation in SOA from terpene ozonolysis (Reinhardt et al., 2007; Walser et al., 2008; Muller et al., 2009). Aldol condensation in isolation does not explain the formation of all the observed masses, with around one third of observed peaks missing (Fig. 9c). Aldol condensation has been found to be favourable thermodynamically (Barsanti et al., 2004) but may be acid catalysed (e.g. Kroll et al., 2008), probably not representative of our experimental conditions. Esterification reactions result
in a modelled dimer mass distribution in very good agreement with the observed ESI-MS spectrum (Fig. 9d), although most of the highest masses ([R+Na]+ adducts at m/z>400) are not present in the simulated dimer spectrum. This correlates with the lack of the simulated masses in the monomer region observed by the ESI-MS for [R+Na]+ adducts at m/z between 240 and 270, resulting in a subsequent lack of dimer masses of [R+Na]+ adducts at m/z around 400 and 460. Esterification reactions are thermodynamically viable (Barsanti et al., 2006).

Figure 10 shows examples of the simulated dimer structures for the m/z peak with the highest intensity observed by ESI-MS (i.e. [R+Na]+ adduct at m/z 391, M=368 g mol⁻¹). Muller et al. (2009) have chemically analysed the structure of species having this molar mass. A dimeric species formed by esterification and highlighted in red in Fig. 10 is in agreement with the chemical analysis. Each accretion reaction has been investigated independently here whereas in practice these reactions could very well occur in parallel in the condensed phase. The qualitative agreement apparent in Fig. 9d leads us to infer that esterification reactions between the condensed monomers may be the dominant processes forming dimeric species during α-pinene ozonolysis experiment. We note however that the various dimeric species will differ in stability. Peroxyhemiacetals are likely to be thermally labile and unstable compounds (Jang et al., 2002; Surratt et al., 2006). During ESI, samples are subjected to temperatures of up to 350 °C within the ion source. Any thermally labile groups may therefore fragment during analysis. For example, we have found that many peroxide standards probed using this technique fragment by loss of water within the source and are effectively unobservable. Such fragmentation may also potentially convert dimers back to monomers, or indeed to different monomers. This may account for some of the low molecular weight peaks that cannot be explained using known reaction mechanisms noted in Sect. 5.2.3. In addition, neutral oligomers (including some peroxyhemiacetals) are not ionisable using the ESI source. Esters would then be the main species observed by ESI-MS due to their stability and ionisation efficiency.

6 Conclusions

SOA formation from dark α-pinene ozonolysis has been studied with an emphasis upon the composition of gaseous and condensed phase SVOC, interpreted qualitatively in terms of their measured and simulated mass distributions. In the course of EUPHORE chamber simulations, the gas-phase oxygenated organic product evolution and distribution was followed using an online CIR-TOF-MS. The semi-volatile oxygenated organic distribution in the condensed phase was acquired through off-line ESI-MS analysis of SOA filters taken at the end of the experiment. A detailed chamber box model designed to simulate SOA formation has been
developed for comparison with the experimental results, coupling an equilibrium gas/particle partitioning module to the \(\alpha\)-pinene oxidation scheme extracted from the MCMv3.1.

The simulated temporal profile of SOA mass for these specific \(\alpha\)-pinene ozonolysis experiments is in reasonable agreement with the observations, both in terms of the shape and magnitude, when vapour pressures of SVOC are calculated using the Myrdal and Yalkowsky method with Joback boiling point estimates. A sensitivity analysis showed that the large differences in published model performances with respect to the simulation of the temporal evolution of SOA mass formation from \(\alpha\)-pinene ozonolysis may be largely a consequence of the use of different methods for SVOC vapour pressure estimation. Reduction in the uncertainties associated with vapour pressure estimates is crucial for the development of reliable organic gas/particle partitioning; however the evaluation of vapour pressure estimation methods for the purpose of SOA modelling is still limited by the availability of experimental data for organic species of interest, i.e. oxygenated species bearing hydroperoxide or nitrate moieties and multifunctional species having vapour pressures lower than \(10^{-6}\) atm.

Recent results however suggest that the Myrdal and Yalkowsky approach coupled with Joback may systematically underestimates vapour pressures, and indicate that alternative approaches such as the Nannoolal methods are more accurate. Their adoption leads to vapour pressures lowered by one to two orders of magnitude, and results in a significant model underestimate of the observed SOA mass. This underestimate may then be compensated for by...

---

**Fig. 10.** Example of structures for dimer species formed from accretion reactions of the simulated monomers for the major peak detected by the ESI-MS (i.e. \([R+Na]^+\) adduct at \(m/z\) 391, \(M=368\) g mol\(^{-1}\)). The chemical structure in agreement with the chemical analysis of Muller et al. (2009) is highlighted in red.
omission of pathways forming SVOC from the MCM chemical scheme for α-pinene oxidation, and/or by reactions in the condensed phase forming larger species with lower volatility. Some evidence for the occurrence of recently suggested peroxy-radical isomerisation channels is found in the mass spectral data. A sensitivity study into the dependence of the simulated SOA mass upon the timescale of oligomerisation indicated that, other uncertainties notwithstanding, a lifetime for SVOC in the condensed phase of the order of 5 min was required to bring the simulated SOA mass into agreement with the observed levels. Time-resolved measurements of SOA composition are needed to give constraints on the timescales of condensed phase reactivity.

Comparisons of the simulated mass spectrum with the CIR-TOF-MS mass spectrum show a similar mass distribution for gaseous organics. The simulated composition for the major peaks detected by the CIR-TOF-MS is in agreement with previous identifications of products formed during α-pinene ozonolysis. Identification of the main peaks of gaseous SVOC present in the CIR-TOF-MS spectrum has been proposed on the basis of the simulated composition. The ESI-MS measurements show the presence in the condensed phase of monomer and oligomer type organics. Comparisons of the simulated condensed phase mass spectrum with the ESI-MS mass spectrum show that most of the peaks in the monomer region are in reasonable agreement, i.e. explained in the simulation by the gas/particle partitioning of SVOC formed during the gas-phase oxidation of α-pinene. A chemical structure for the principal condensed-phase monomers detected has been proposed on the basis of the simulated composition and known LC-MS fragmentation patterns.

Oligomer species detected by the ESI-MS are likely to be the result of accretion reactions occurring in the condensed phase and/or in the gaseous phase. The possible influence of a range of accretion reactions occurring in the condensed phase on the mass distribution of condensed dimers has been explored independently, drawing upon the simulated composition of the condensed monomers. Accretion reactions investigated were: peroxyhemiacetal formation, hemiacetal formation, aldol condensation and esterification. Comparisons of the simulated mass distribution of dimers with the observed mass spectrum suggest that esterification reactions are the dominant process involved in this system. This approach offers a route to identifying the SVOC leading to SOA formation by gas/particle partitioning, which may in turn allow their chemical ageing to be simulated on timescales which are experimentally inaccessible. Extending this approach to characterising the gaseous and particulate organic composition from other organic precursors and under various experimental conditions will help correctly understand SOA formation, and therefore assist in the development of reliable SOA schemes in 3-D chemical transport models.
